Often certain nodes in the network are randomly switched off, from some or all the layers of a neural network. Hence, in every iteration, we get a new network and the resulting network (obtained at the end of training) is a combination of all of them. This also helps in addressing the problem of overfitting.

Artificial neural networks for solving ordinary and partial differential equations. Abstract: We present a method to solve initial and boundary value problems using artificial neural networks. A trial solution of the differential equation is written as a sum of two parts. The first part satisfies the initial/boundary conditions and contains no adjustable parameters.

The primary constructs of neural networks are weights and biases between different neurons. Weight decay engages selective weights that reduce while moving towards the output layers. As the weight decays, overfitting reduces enabling generalization.

A neural network simply consists of neurons (also called nodes). These nodes are connected in some way. Then each neuron holds a number, and each connection holds a weight. These neurons are split between the input, hidden and output layer.

Gradients of neural networks are found using backpropagation. Simply put, backpropagation finds the derivatives of the network by moving layer by layer from the final layer to the initial one. By the chain rule, the derivatives of each layer are multiplied down the network (from the final layer to the initial) to compute the derivatives of the initial layers.

The-Vanishing-Gradient-Problem—The-Problem-Its-Causes—
Backpropagation is an algorithm commonly used to train neural networks. When the neural network is initialized, weights are set for its individual elements, called neurons. Inputs are loaded, they are passed through the network of neurons, and the network provides an output for each one, given the initial weights.
